Keywords: β -lactoglobulin, food allergen, food processing, Maillard reaction, uptake and degradation by DCs

ABSTRACT

Scope

During food processing the Maillard reaction (MR) may occur resulting in the formation of glycated proteins. Glycated proteins are of particular importance in food allergy since glycation may influence interactions with immune system. This study compared native and extensively glycated milk allergen β -lactoglobulin (BLG), in their interactions with cells crucially involved in allergy.

Methods and results

BLG was glycated in MR and characterized. Native and glycated BLG were tested in experiments of epithelial transport, uptake and degradation by DCs, T-cell cytokine responses and basophil cell degranulation using ELISA and flow cytometry. Glycation of BLG induced partial unfolding and reduced its intestinal epithelial transfer over a Caco-2 monolayer. Uptake of glycated BLG by bone marrow-derived dendritic cells (BMDC) was increased, although both BLG forms entered BMDC via the same mechanism, receptor-mediated endocytosis. Once inside the BMDC, glycated BLG was degraded faster, which might have led to observed lower cytokine production in BMDC/CD4⁺ T-cells coculture. Finally, glycated BLG was less efficient in induction of degranulation of BLG-specific IgE sensitized basophil cells.

Conclusions

This study suggests that glycation of BLG by MR significantly alters its fate in processes involved in immunogenicity and allergenicity, pointing out the importance of food processing in food allergy.

1. INTRODUCTION

Nowadays, the majority of food is subjected to thermal treatment prior to consumption, which induces structural and chemical modifications of food proteins. One of the most widespread modifications is glycation by the Maillard reaction (MR), a very complex reaction cascade that occurs between amino and carbonyl groups ^[1]. Products of MR are very diverse and give rise to a variety of glycation structures covalently attached to food proteins that are collectively termed as Advanced Glycation Endproducts (AGEs). Glycated proteins possess many functional properties that are relevant for food industry such as improved gelling, emulsifying and foaming activity, increased temperature and pH stability and increased antioxidant activity ^[2-6], but also characteristics that are attractive for consumers such as appealing color, smell, taste and texture ^[7].

Apart from improving techno-functional properties, MR also alters biological and immunological properties of food proteins. It is well documented that glycation of food allergens affects their IgE binding ability by direct masking of linear as well as conformational epitopes, leading to reduced allergenicity ^[8, 9]. In contrast, other studies have pointed out that glycation led to formation of neoantigens, hereby increasing their recognition by IgE antibodies ^[10-12]. Recently, evidences are emerging that effects of MR on food allergens go beyond IgE recognition. Dendritic cells (DCs), as the most important antigen-presenting cells in the immune system, possess several receptors that recognize glycation structures, including receptor for Advanced Glycation Endproducts (RAGE), Scavenger Receptors (SRs), galectin-3 and CD-36 ^[13, 14]. Acting through these receptors, glycation structures may influence recognition, uptake and processing of food allergens by DCs. Subsequently, this may have consequences on the maturation of DCs and subsequent activation of naïve T-cells. For instance, a glycated form of the major egg allergen, ovalbumin (OVA) binds to SR class A which mediates increased allergen uptake by DCs, and

leads to a stronger T helper type 2 cytokine response^[15, 16]. Similarly, AGE-BSA induced maturation of DCs and augmented their capacity to stimulate T-cell proliferation and cytokine secretion^[17]. It has even been speculated that AGEs of food allergens interact with DCs, promote immune responses and contribute to development of food allergy by mimicking endogenous danger signals^[18].

Very little is known about allergen processing and degradation inside DCs, despite that this is of great importance. It has been described that the dynamics of uptake and degradation inside endolysosomal compartments of DCs affects class II MHC loading pathways, antigen presentation and finally T-cell polarization^[19-21].

β -Lactoglobulin (BLG) is the most abundant whey protein and one of the major allergens in milk^[22]. Whey proteins are frequently used as food additives because of their valuable nutritional and techno-functional properties. Thus, they are very likely to be glycated in MR upon food processing. There are scarce literature data about the effects of the MR on the immunogenic properties of the major whey allergen. Hence, the aim of this study was to glycate BLG with glucose to a high extent and to conduct a comparative analysis, relative to its native form, regarding their behavior in processes that are involved in immunogenicity and allergenicity. Intestinal epithelial transcytosis, uptake and degradation by BMDCs, ability to induce cytokine production by BLG-specific CD4⁺ T-cells and basophil degranulation capacity of native and glycated BLG were investigated.

2. METHODS

2.1. Chemicals and standards

Unless otherwise stated, all chemicals were obtained from Sigma-Aldrich (St. Louis, MO, USA). For all experiments Milli-Q water (Millipore, France) was used.

2.2. Mice

Five-week-old female C3H/HeOuJ mice were purchased from Charles River (France) and were maintained in specific pathogen-free conditions within the animal care facility at the Utrecht University. Experiments were approved by the Animal Experiments Committee of the Utrecht University.

2.3. Protein sample preparation

BLG was isolated from raw cow's milk as described previously ^[23] (details are given in supplementary material). Purity of the obtained BLG preparation was estimated to be >95% by SDS-PAGE. Protein concentration was determined by bicinchoninic acid (BCA) assay (Pierce, Amsterdam, The Netherlands). Endotoxin was reduced from samples by affinity chromatography on ϵ -poly-L-lysine cellulose beads (Thermo Scientific, Rockford, IL). The residual amount of endotoxin was determined using LAL Chromogenic Endotoxin Quantitation Kit (Thermo Scientific, Rockford, IL). The endotoxin concentration in BLG sample was 0.4 EU/mg of protein.

2.4. Glycation procedure and characterization of glycated BLG

Glycated BLG was made by performing the MR in which 10 mg/ml BLG was incubated with 180 mg/ml glucose in 50 mM phosphate buffer, pH 8.0 at 60°C for 10 days in capped vials. Thermally treated BLG under the same conditions but without glucose was also prepared. To determine the degree of glycation, free amino groups were estimated by the ortho-phthalaldehyde (OPA) method as described previously ^[24]. To further characterize glycated BLG, SDS-PAGE was performed on 14% gel (5 μ g of protein per lane, under reducing and non-reducing conditions. Protein bands were visualized by Coomassie Brilliant Blue staining. Structural changes were monitored by recording far-UV CD spectra on a JASCO J-815 spectropolarimeter (JASCO, Tokyo, Japan) of 0.85 mg/ml native and glycated BLG in 50 mM sodium phosphate buffer pH 8.0. Each spectrum was acquired four times, and the results were averaged. Spectra were analyzed by the CONTIN program to determine the proportion

of secondary structures based on reference protein set of 29 soluble proteins – SP29 as previously was done ^[23].

2.5. Caco-2 cell culture

The culturing of Caco-2 cells is described in Supplementary material.

2.6. Transport across Caco-2 cell monolayer

For transport studies, Caco-2 cells were seeded at 1.6×10^4 cells/insert on polycarbonate membranes with a pore size of 0.1 μm in 24-well plates (Transwell, Corning Costar, Cambridge, MA). Cells at passages of 17-25 were used in experiments. Prior to the transport studies transepithelial electrical resistance (TEER) was measured using Millicell-ERS VoltOhmmeter (Millipore, Amsterdam, The Netherlands). Only cell monolayers with TEER > 500 Ω were used. Native and glycosylated BLG were diluted in DMEM culture medium to a final concentration of 1.5 mg/ml, and 100 μl of these preparations were loaded onto apical surface of Caco-2 monolayer, while 600 μl of DMEM culture medium was added to the receiver compartment. Aliquots of 30 μl were withdrawn from the receiver compartment after 15, 30, 60, 120, 240, and 300 min and receiver compartment was replenished every time with medium. Transported native and glycosylated BLG were detected by commercially available ELISA kit (Bethyl Laboratories, Inc., Montgomery) according to manufacturer's instructions.

2.7. Generation of Bone Marrow-derived Dendritic Cells (BMDCs)

Bone marrow cells isolated from femurs/tibias of naïve C3H/HeOuJ mice were cultured in conditioned- complete DCs medium (RPMI 1640 medium glutamax (Gibco, Invitrogen, Carlsbad, USA)) supplemented with 10% heat-inactivated FCS, 1 mM sodium pyruvate, 100 units/ml penicillin, 100 $\mu\text{g/ml}$ streptomycin, 1% nonessential amino acids, 0.1 mM 2-mercaptoethanol, with 10 ng/ml GM-CSF (R&D, Oxon, UK) at 37 °C in a humidified atmosphere of 5% CO₂. Medium was refreshed on day 3. Only 6-day old BMDCs were used for the following experiments.

2.8. Allergen uptake by BMDCs

Native and glycosylated BLG were labeled with FITC according to the manufacturer's instructions (Sigma-Aldrich, St. Louis, MO, USA). FITC-native BLG and FITC-glycosylated BLG conjugates were separated from unreacted FITC label using PD-10 desalting column (GE Healthcare, Uppsala, Sweden). The labeling efficacy was the same for native and glycosylated BLG as determined by absorbance at 280 and 495nm. The concentration of labeled samples was determined by BCA assay, and the samples were stored protected from light at 20 °C until use.

FITC-native and FITC-glycosylated BLG (10 µg/ml) were incubated with 1×10^6 BMDCs/ml of cell culture medium for 0, 5, 10, 20, 30, 45, 60, 90 and 120 min at 37 °C. Uptake was recorded using BD Accuri C6 Cytometer (BD Biosciences, San Jose, CA, USA). Mean fluorescence intensity (MFI) and percentage of FITC-positive BMDCs were calculated using BD Accuri C6 software.

2.9. Mechanistic studies of allergen uptake by BMDCs

To identify uptake mechanism for native and glycosylated BLG, BMDCs were pretreated with 10 µg/ml latrunculin B, 1 µM jasplakinolide 2 mM amiloride, 2 µM phenylarsine oxide, inhibitors of phagocytosis, macropinocytosis and receptor-mediated endocytosis, respectively. To inhibit uptake mediated by specific receptors, BMDCs were incubated with the following inhibitors: 100 µg/ml dextran sulfate, or 200 µg/ml polyinosine specific for SRs, and 0.3 µM FPS-ZM1 specific for RAGE. After 30 min of incubation at 37 °C with the above inhibitors, BMDCs were loaded with 10 µg/ml FITC-native BLG and FITC-glycosylated BLG. Uptake was recorded after 30 min of incubation at 37 °C by flow cytometry as described above.

2.10 Confocal microscopy

1x10⁵ BMDCs in the presence or absence of different inhibitors under above described conditions were withdrawn, washed and spun onto glass slides by cytopsin. Cells were imaged on a Leica TCS SPE-2 confocal laser scanning-microscope on a DMI4000.

2.11. Endolysosomal degradation assay

Native and glycated BLG were covalently coupled to polystyrene beads (Polysciences, Inc., Warrington, PA, USA) (protocol included in Supplementary material).

Endolysosomal degradation was estimated according to Hoffmann E. et al. [25] with minor modifications. Total of 12.5 x 10⁶ of BMDCs from naïve mice were incubated with 50 x 10⁶ of native and glycated BLG-coated beads at 37 °C for 15 min to allow phagocytosis.

Phagocytosis was stopped by adding ice-cold PBS. Non-internalized beads were washed out 3 times with FCS floatation cushion at +4 °C. BMDCs were resuspended in 2.5 ml of conditioned-complete DCs medium and incubated at 37 °C to start phagosome maturation.

Aliquots of 480 µl were withdrawn after 0, 30, 120, 240 and 720 min and immediately mixed with 1 ml of ice-cold PBS to stop phagosome maturation, and centrifuged for 5 min at 400g at 4 °C. Pelleted BMDCs were lysed with lysis buffer (50 mM Tris, 150 mM NaCl, 0.5% Triton x, 1 mM DTT, 10 µg/ml Dnase I, pH 7.4, with addition of complete protease inhibitor cocktail (Roche, Lewes, UK)), overnight, at 4 °C. Non-degraded BLG on the beads surface was detected using rabbit polyclonal anti-BLG antibody 1:1000 (Fitzgerald, 70R-LR011) and anti-rabbit Alexa 488 antibody (Invitrogen A11034). Alexa intensity was measured by flow cytometry.

2.12. Assessment of T-cell Activation and Cytokine Production

BLG-specific CD4⁺ T-cells were obtained from spleens of C3H/HeOuJ mice immunized with BLG and aluminum hydroxide (Imject Alum, Pierce, Netherlands). On days 0 and 7, three mice were intraperitoneally injected with 100 µg of native BLG and 1 mg of ALUM. On day 14, BMDCs from naïve mice were primed with 50 µg/ml of different forms of BLG for 2 h.

BMDCs were scraped, washed, and transferred to a 48-well plate where they were cocultured (1:10 cell number ratio) with freshly isolated CD4⁺ T-cells for the next 72 h. Subsequently, levels of IFN- γ , IL-5, IL-10 and IL-13 were measured in coculture supernatants by commercially available ELISA (e-Bioscience, Austria).

2.13. Anti-BLG IgE crosslinking-induced NFAT-responsive luciferase in basophilic RS-ATL8 cells

The humanized rat basophilic leukemia cell line RS-ATL8 was kindly provided by R. Nakamura from the National Institute for Health Sciences, Tokyo, Japan. This cell line which was established by introducing the NFAT-responsive luciferase gene into human Fc ϵ RI expressing RBL-SX38 cells was used to measure IgE crosslinking-induced luciferase expression (EXiLE). EXiLE assay was performed as described previously ^[26] with slight modifications. RS-ATL8 cells (5×10^4 cells/50 μ l/well) in 96-wells flat bottom culture plate were sensitized overnight with a pool of six anti-BLG chimeric IgE monoclonal antibodies (1 μ g/ml each individual humanized IgE) ^[27]. Cells were washed once with sterile PBS and then stimulated for 1h at 37 °C in a 5% CO₂ incubator with 50 μ l/well of native and glycated BLG diluted in MEM containing 10% FCS in four different concentrations (1, 10, 100 and 1000 ng/ml) or with 1 μ g/ml goat anti-human IgE antibodies (DakoCytomation, Glostrup, Denmark) as control. After stimulation, 50 μ l of luciferase substrate solution containing cell lysis reagent (ONE-Glo, Promega Corp., Tokyo, Japan) was added to the cells, and chemiluminescence was measured. Luciferase expression levels are represented as the fold increase of relative light units compared with the background expression.

2.14. Statistical analysis

Data are presented as mean \pm stand deviation (SD) or standard error of mean (SEM) and analyzed using GraphPad Prism software (La Jolla, CA). Data were tested by Student's t-test. Differences were considered significant when *p*-values were <0.05.

3. RESULTS

3.1. BLG was glycosylated to a high extent accompanied by modifications in secondary structure.

BLG was glycosylated with glucose in the MR, and the degree of glycosylation was assessed by determining the free amino group content by OPA method (Fig. 1A). A significant loss of available amino groups was observed; about 75% of amino groups were glycosylated. Analysis of native and glycosylated BLG by SDS-PAGE showed a band at 18 kDa, corresponding to BLG (Fig. 1B). This band smeared toward higher molecular masses after conjugation with glucose molecules. Under non-reducing conditions, BLG dimers were present in both, native and glycosylated BLG, while under reducing conditions, native BLG was visible only in monomeric form, but glycosylated BLG was still visible in dimeric form, indicating the formation of covalent bonds other than disulfide bridges. Glycosylation reaction also induced covalent aggregates formation, noticeable as higher molecular masses at the interface of stacking and running gels. Changes were observed in far-UV CD spectra of glycosylated BLG compared to native BLG spectra (Fig. 1C). The characteristic minimum of native BLG at 215 nm was shifted toward a lower wavelength, indicating a decrease in the ordered secondary structure. Software analysis of CD spectra showed a decrease in α -helix accompanied with an increase in random coils (Fig. 1D), suggesting a direct conversion of regular into irregular structures upon glycosylation. In addition, thermal treatment of BLG without glucose led to different changes in structure and a higher extent of aggregate formation in comparison to glycosylated BLG, as evidenced by SDS-PAGE under reducing and non-reducing conditions (Fig. S1A and B). Also, far-UV CD spectra analysis showed differences in the structural change of heated and glycosylated BLG in comparison to native BLG. Heated BLG showed a significantly higher loss of β -sheets (Fig. S2A and B). The protective effect of sugar on the heat-induced denaturation and aggregation

of BLG has been shown extensively before [5, 24, 28, 29]. Therefore structural changes induced by Maillard reaction are not simple the sum of thermally induced structural changes and covalent attachment of sugar moieties. Thus, native BLG, rather than heated BLG, was used as control in order to compare their interactions with immune cells crucially involved in cow`s milk allergy.

3.2. Glycation of BLG reduced transport across Caco-2 cell monolayer.

Transport of BLG samples across Caco-2 cell monolayer, a model of intestinal barrier function, was examined. Native and glycated BLG were applied on apical side of Caco-2 cells and transport was followed in time by determining BLG concentration on basal side. Glycation reaction dramatically reduced detection of BLG at basolateral side of Caco-2 monolayer (Fig. 2). Transport of both native and glycated BLG was continuous, verifying intactness of Caco-2 monolayer and preserved tight junctions during experiment.

3.3. Glycation of BLG increased uptake by BMDCs.

Further, we investigated whether glycation through MR influences interactions of BLG with BMDCs. FITC-labeled native and glycated BLG were incubated with BMDCs, and BLG uptake was followed in time by flow cytometry. Uptake of both BLG forms, measured as percent of FITC-positive cells (Fig. 3A) was time dependent and reached plateau after 30 minutes, while the MFI (Fig. 3B) continuously increased up to 120 minutes. Glycated BLG was taken up more efficiently reaching 85% of FITC-positive BMDCs compared to 55% when incubated with native BLG. Significantly increased uptake of glycated BLG was also observed when MFI was measured.

Confocal micrographs were in agreement with the findings obtained by flow cytometry, BMDCs displayed a higher fluorescent signal upon incubation with glycated BLG (Fig. 3C).

3.4. Glycated BLG entered BMDCs via receptor-mediated endocytosis, involving scavenger receptors.

To understand the process of uptake by BMDCs of native and glycated BLG, we inhibited several possible uptake routes. First, BMDCs were incubated at 4 °C to stop all active cellular processes. This led to almost complete reduction of native and glycated BLG uptake (Fig. 4A), indicating that the uptake was active and by an energy dependent process. Second, pretreatment with latrunculin B and jasplakinolide, which are known to interfere with actin polymerization and therefore inhibit phagocytosis, reduced uptake of both BLG forms (Fig. 4A and C). This suggested that actin and phagocytosis were involved in the uptake process. Third, amiloride, an inhibitor of macropinocytosis, also decreased uptake of both BLG forms (Fig. 4A and C). Final, pretreatment of BMDCs with phenylarsine oxide, an inhibitor of the internalization of cell surface receptors, resulted in a strong inhibition of the endocytosis of native BLG, while almost completely abrogated uptake of glycated BLG (Fig. 4A and C). Taken together, inhibition studies showed that native and glycated BLG entered BMDCs in actin-dependent process and phagocytosis, by constitutive macropinocytosis and by receptor-mediated endocytosis. Additionally, in an attempt to identify receptor(s) involved in the uptake of native and glycated BLG, inhibitors for specific endocytic receptors were used. Both dextran sulfate and polyinosine, inhibitors of SRs, remarkably reduced the uptake of both BLG forms (Fig. 4B and D). Treatment of BMDCs with FPS-ZM1, a RAGE inhibitor, did not significantly affect uptake of any BLG form (Fig. 4B and D). This suggests that both BLG forms bind to and being internalized via SRs at least to some extent. Redirection of glycated BLG uptake towards receptor-mediated endocytosis could be caused by stronger recognition by SRs due to changes in physicochemical properties that followed the MR.

3.5. Glycated BLG showed higher susceptibility to endolysosomal degradation inside BMDCs.

Efficient intracellular antigen degradation and processing is of crucial importance for antigen presentation. We therefore compared endolysosomal proteolysis of native and glycated BLG within BMDCs. BMDCs were allowed to phagocytose native and glycated BLG coupled to polystyrene beads, and endolysosomal degradation of allergens was determined by BLG-specific antibody binding. Significant lower antibody binding to glycated BLG after first 30 min of degradation indicated that glycation influenced degradation kinetics, making glycated protein more susceptible to proteolysis especially at first time (Fig. 5).

3.6. Glycated BLG induced lower CD4⁺ T-cell cytokine responses.

To assess the specific T-cell responses to glycated BLG, BLG-specific CD4⁺ T-cells were isolated from mice immunized to native BLG and cocultured with BMDCs primed with native or glycated BLG. After coculture, glycated BLG-primed BMDCs induced lower production of INF- γ , IL-5 and IL-13 by T cells, when compared with native BLG-primed BMDCs (Fig. 6). Both native and glycated BLG-primed BMDCs equally induced IL-10 production.

3.7. Glycation of BLG reduced basophil activation

Finally, to gain insight into the effects of glycated BLG on allergic effector responses, a basophil cell elicitation test was performed. RS-ATL8 cells were sensitized with oligoclonal anti-BLG specific humanized IgE antibodies and subsequently native or glycated BLG was added. Glycated BLG induced significantly lower basophil activation compared to native BLG at all tested concentrations (Fig. 7).

4. DISCUSSION

Thermally processed food is highly consumed in the Western diet nowadays. Food processing can induce multiple biochemical reactions in food including MR which cause glycation of food proteins and formation of AGEs. Glycation of food allergens may have an impact on allergenicity but there is no conclusive data on how these modifications alter

allergenic manifestations. The immunomodulatory effects of AGEs structures have been described in literature (reviewed in ^[18, 30-33]). For instance, the effects of MR on immunogenicity and allergenicity of food allergen OVA have also been studied and have shown an elevated risk of food allergy ^[15, 16, 34]. We aimed to describe how glycation reaction of the major milk allergen, BLG, influences handling and processing by epithelial and dendritic cells.

In order to exert a possible immunological effect, glycated proteins must be able to pass the intestinal epithelial barrier and to get in contact with immune system. Transport of allergens can occur transcellularly or paracellularly through intestinal epithelial cells. The main route of *in vivo* intestinal absorption of native BLG is through epithelial cells ^[35, 36]. We compared the transfer of native and glycated BLG using the well-known *in vitro* Caco-2 cell monolayer system for testing intestinal barrier function. We showed that both native and glycated BLG are able to cross the Caco-2 monolayer, although the MR drastically reduced transcytosis of BLG. This could have been caused by the physicochemical changes in BLG induced by glycation, such as partial unfolding, and formation of high molecular weight species which can make transcytosis more difficult. Reduced intestinal permeability would result in lower allergen uptake and may hence reduce activation of sensitized *lamina propria* mast cells and subsequent anaphylactic responses ^[37]. Roth et al. reported that pasteurization of the BLG and α -lactalbumin protected against an anaphylactic reaction, since uptake through epithelial cells was impaired due to aggregation ^[36]. Furthermore, in our basophil activation experiments, glycation of BLG reduced its capacity to crosslink Fc ϵ RI receptors on RBL cells. In extensively glycated BLG all residues containing free amino group (16 lysines, 2 arginines and N-terminal amino group of Leu 1) seem to be glycated ^[38, 39], while all of the BLG-specific chimeric human IgE monoclonal antibodies used in this study recognize peptides containing at least 1-2 residues with possible glycation sites^[27]. Therefore, it is

highly likely that extensive BLG glycation reduced mAb IgE binding by changing epitope structure, and led to reduced basophil activation. Additionally, previous studies showed a masking effect of glycation with different monosaccharides on IgE binding properties of BLG [8]. This effect of high degree of glycation on recognition of food allergens by IgE antibodies has been well documented in literature [8, 9, 40]. Lower allergic effector responses (as measured by ability to induce crosslinking of FcεRI receptors), together with much lower intestinal transport (as measured in transcytosis Caco-2 experiment) suggest that glycation of BLG reduces the risk of allergic or even anaphylactic reactions.

To further characterize the down-stream processing of glycated BLG we examined its uptake and degradation by murine BMDCs. We found that the uptake of glycated BLG by immature BMDCs was significantly increased, compared to uptake of native BLG, at every measured time-point. The same was observed for uptake of glycated OVA by either murine BMDCs or human myeloid DCs [15, 16, 34]. In addition, we used pharmacological inhibitors which interfere with different internalization pathways. Phenylarsine oxide inhibited the uptake of both native and glycated BLG, indicating that receptor-mediated endocytosis is involved in internalization process. The more pronounced inhibition of glycated BLG uptake, compared to inhibition of native BLG uptake, in the presence of phenylarsine oxide indicates a shift of glycated BLG uptake to receptor-mediated endocytosis. To execute their role, BMDCs are equipped with a full array of specialized receptors, including pattern-recognition receptors (PRRs) such as Toll-like receptors (TLRs), C-type lectins (CTLs) and SRs. Literature suggests that some allergens interact with PRR and hereby stimulate innate and adaptive responses [41]. Considering their role in recognizing glycated products we selectively blocked SRs and RAGE and found that SRs were responsible for the uptake of both native and glycated BLG. Our findings are in accordance with previously published data that AGEs structures of glycated proteins bind to SR class A [34, 42]. Interestingly, SRs ligands are

371 polyanionic molecules ^[43] and BLG is an acidic protein with pI value 5.1, which can explain
372 its binding to SRs. Blocking of lysyl residues by sugar moieties in MR lowers pI value and
373 makes glycated BLG even more acidic, possibly leading to higher binding affinity for SRs
374 and consequently higher uptake by BMDCs. Another factor influencing faster uptake could
375 be changed folding and increased aggregation that accompanied the glycation reaction.
376 Similarly, pyrraline, an AGEs structure, when attached to OVA has been suggested to
377 promote SR class A-mediated allergen uptake by DCs ^[34].
378 In spite of the much higher uptake by BMDCs through SR-mediated endocytosis, glycated
379 BLG showed lower CD4⁺ T-cell stimulation. Glycated BLG-primed BMDCs in coculture
380 with BLG-specific CD4⁺ T-cells showed significantly lower production of Th1- (INF- γ) and
381 Th2-type cytokines (IL-5 and IL-13) when compared with native BLG-primed BMDCs. This
382 indicated that there was less peptide loading of MHC class II when BMDCs were primed
383 with glycated BLG. Previously published results, showing that glycated OVA was taken up
384 by DCs via SR class A type I and type II-mediated endocytosis, followed with enhanced
385 CD4⁺ T-cell responses ^[15], are in contrast with our findings and indicate that overall effect on
386 T-cell responses is carbohydrate- and allergen-dependent. These findings also stress the
387 importance of events that follow antigen internalization i.e. antigen processing and activation
388 of downstream signaling pathways. In support of our observations, Smole et al. reported that
389 immature monocyte-derived DCs were able to internalize potent allergen Bet v 1 and its
390 structural homolog, but weak allergen, Api g 1 with the similar kinetics, and furthermore,
391 there was no difference in the uptake by DCs from healthy or allergic donors ^[44]. We showed
392 increased susceptibility of glycated BLG to endolysosomal proteolysis. Glycation of BLG
393 increased content of random structures (as shown by CD spectroscopy), reducing it's fold
394 stability and making polypeptide backbone more accessible to endolysosomal proteases.
395 Intracellular antigen degradation in antigen presenting cells determines the antigen fate ^[45].

Antigens highly susceptible to endolysosomal proteases are known to possess weak capacity of T-cell priming ^[46]. This could explain the observed decreased T-cell stimulation by glycated BLG.

In conclusion, in this study, we found that BLG glycated in MR showed reduced transepithelial transport, but higher uptake by BMDC. It appeared that both native and glycated BLG can be endocytosed by BMDCs via SRs, but MR made BLG a better ligand for SRs possibly through lowering pI value and aggregates formation and thus increased its uptake. Glycated BLG was more prone to endolysosomal degradation and showed lower potential to induce cytokine production in coculture of BMDCs with BLG-specific CD4⁺ T-cells. Glycated BLG also induced lower effector response i.e. reduced basophil activation. Altogether, our results showed that glycation of BLG influences its interactions with cells involved in the (allergic) immune response, and also that glycated BLG could be less potent in the induction of Th2 type responses in a host primarily sensitized to native BLG. Interestingly, up to now literature data about sensitizing potential of glycated BLG is still missing. Future studies are needed to elucidate importance of MR on allergenicity and immunogenicity of BLG *in vivo*. The present study contributes to the knowledge regarding the effects of food processing on food allergies and it is of great importance for considerations of pros and cons of food processing.

AUTHOR CONTRIBUTION

M.P. participated in all stages of the project, did the experiments, interpreted data and was the main author of the manuscript; M.R. participated in carrying out the experiments; D.S.V., P.J.S., R.P., T.C.V. contributed with interpretation of the data; J.J.S. designed the study and interpreted data. All authors contributed to the manuscript.

ACKNOWLEDGMENT

This work was supported by the GA No. 172024 of the Ministry of Education, Science and Technological Development. Marija Perusko's research visit to the Institute for Risk Assessment Sciences was supported by COST Action FA1402. We thank to R. Nakamura (National Institute of Health Sciences, Tokyo, Japan) and F. H. Falcone (University of Nottingham, Nottingham, United Kingdom) for supplying the RS-ATL8 reporter system.

CONFLICT OF INTEREST

None.

FIGURE LEGENDS

Figure 1. Characterization of BLG glycosylated in MR. (A) Estimation of the degree of MR by determining remaining free amino group content by OPA method. Free amino group content was statistically compared by Student's t-test. **** denotes significance at $p < 0.0001$ confidence level. (B) Protein profile of native and glycosylated BLG on 14% SDS-PAGE gel under non-reducing (NR) and reducing (R) conditions. Protein bands were stained with CBB. 1: native BLG; 2: glycosylated BLG; 3: molecular weight markers (kDa). (C) CD spectra of native and glycosylated BLG in far-UV spectral range. Samples were recorded in 50 mM sodium phosphate buffer, pH 8.0 at protein concentration 0.85 mg/ml. (D) Percentages of the secondary structures were estimated by CONTIN algorithm available in CDPro package based on SP29 reference set. Secondary structure fractions were compared by Student's t-test. * represents significance at $p < 0.05$ confidence level.

Figure 2. Bioavailability of native and glycosylated BLG *in vitro*. Transcytosis of native and glycosylated BLG across Caco-2 monolayer. Transport was measured by determining BLG concentration in samples withdrawn from basolateral chamber at different time-points up to 3 h. Each point represents the mean \pm SD. One representative experiment out of three independent is shown. *, ** and ***, represent significance at $p < 0.05$, 0.01 and 0.001, respectively.

Figure 3. BMDCs uptake of FITC labeled native and glycosylated BLG followed in time. BMDCs were incubated with 10 μ g/ml FITC labeled native and glycosylated BLG for 120 minutes and the BMDC uptake was analyzed by means of flow cytometry. Data are expressed as A) percent of FITC positive BMDCs and B) MFI. **, and ****, represent significance at $p < 0.01$ and 0.0001, respectively. (C) Confocal micrographs of BMDC incubated with FITC labeled native and glycosylated BLG for 30 minutes.

Figure 4. Mechanistic studies of uptake of FITC labeled native and glycated BLG in presence of different inhibitors. BMDCs were pre-incubated for 30 minutes with (A) mechanism specific inhibitors, namely: latrunculin B – inhibitor of actin polymerization; jasplackinolide – inhibitor of phagocytosis; amiloride – macropinocytosis inhibitor; phenylarsine oxide – inhibitor of receptor-mediated endocytosis, or with (B) receptor specific inhibitors: dextran sulfate and polyinosine – SRs inhibitors; FPS-ZM1 – RAGE inhibitor. Subsequently, cells were loaded with 10 µg/ml FITC labeled native and glycated BLG. BMDCs uptake was analyzed by flow cytometry, and data are represented as percent of MFI of non-inhibited uptake as mean ± SEM (n = 6) and analyzed by Student's t-tests. **, ***, and ****, represent significance at p<0.01, 0.001, and 0.0001, respectively. Mechanistic studies in the presence of (C) mechanism specific inhibitors or (D) receptor specific inhibitors were additionally followed by confocal microscopy.

Figure 5. Kinetics of endolysosomal degradation of native and glycated BLG. BMDC were allowed to internalize native and glycated BLG-coated polystyrene beads and incubated for different periods at 37 °C to allow endolysosomal degradation. After every time-point cells were lysed and beads carrying non-degraded BLG were stained by Alexa 488 BLG-specific antibodies. Polystyrene beads were analyzed by flow cytometry. (A) Flow cytometry dot plot of one representative experiment. (B) Percentage of non-degraded native and glycated BLG over time is shown as mean ± SEM (n=4). **** denotes significance at p<0.0001 confidence level.

Figure 6. Stimulation of BLG-specific CD4⁺ T-cells by native or glycated BLG-primed BMDCs. CD4⁺ T-cells isolated from C3H/HeOuJ mice immunized with native BLG were cocultured with BMDCs primed with native or glycated BLG for 72 hours. Levels of INF-γ, IL-5, IL-10 and IL-13 in coculture supernatants were measured by ELISA. The data are

presented as mean \pm SD of one representative experiment and analyzed by Student's t-test.

, *, and ns, represent $p < 0.01$, 0.001 , and not significant, respectively.

Figure 7. IgE crosslinking-induced luciferase expression assay demonstrating basophil activation by native and glycated BLG. RS-ATL8 cells sensitized with the pool of BLG-specific chimeric human IgE monoclonal antibodies and subsequently stimulated with 1, 10, 100 or 1000 ng/ml of native and glycated BLG. Luciferase expression level after 1h of stimulation is shown. Dashed line shows luciferase expression after stimulation with 1 μ g/ml anti-human IgE antibodies. Data are expressed as mean \pm SD ($n = 8$) and analyzed by t-tests.

* $p < 0.05$.

Supplementary material

Glycation of the major milk allergen β -lactoglobulin changes its allergenicity by alterations in cellular uptake and degradation.

METHODS

Isolation of BLG from cow's milk

Cow's milk was centrifuged at 4000 x g for 30 min at 4 °C to obtain skimmed milk. Casein was precipitated by lowering pH to 4.6 and removed by centrifugation at 4000 x g for 30 min.

Resulting whey was defatted by tetrachloroethylene extraction (2:1 v/v) and dialysed against 20 mM Tris buffer pH 7.5. DEAE Sephadex A-50 (GE Healthcare, Uppsala, Sweden) was equilibrated with 20 mM Tris pH 7.5 and adsorbed whey proteins were eluted by a salt step gradient ranging from 40 mM to 280 mM NaCl. Fractions containing purified BLG were dialysed against 50 mM phosphate buffer pH 8.0 and concentrated. Purity of the obtained BLG preparation was estimated to be >95% by SDS-PAGE. Protein concentration was determined by bicinoninic acid (BCA) assay (Pierce, Amsterdam, The Netherlands).

Caco-2 cell culture

The human colon cancer cell line, Caco-2, was obtained from American Type Culture Collection (Rockville, MD, USA). Cells were cultured in DMEM (Gibco, Invitrogen, Carlsbad, CA, USA) supplemented with 1% nonessential amino acids, 20% heat-inactivated Fetal Calf Serum (FCS) and 1% of a mixture of penicillin and streptomycin (10 000 units and 10 mg/ml, respectively) at 37 °C in a humidified atmosphere of 5% CO₂. Cells were subcultured weekly after reaching approximately 80% confluence and the culture medium was changed three times per week.

Coupling of native and glycated BLG to polystyrene beads

Polystyrene beads (Polysciences, Inc., Warrington, PA, USA) were pre-activated with 8% (v/v) glutaraldehyde for 4h at room temperature. Approximately 1.7×10^8 beads were conjugated to native and glycated BLG (0.5 mg/ml, 0.5 ml) on a rotating wheel overnight at 4 °C. After quenching unreacted groups with 0.5 M glycine for 30 min, beads were used for endolysosomal degradation assays.

RESULTS

Heated BLG prepared under the same conditions as glycated BLG but in the absence of glucose (10 mg/ml BLG, 50 mM sodium phosphate buffer, pH 8.0, 60 °C for 10 days) was compared to glycated BLG in terms of protein structure and aggregation. In comparison to native BLG, heated and glycated BLG underwent different structural changes. SDS-PAGE analysis under non-reducing conditions (Fig. S1A) showed that heated sample was polymerized, with no free monomer form. Glycated BLG was present in form of monomer, dimer and polymer. Reducing SDS-PAGE (Fig. S1B) revealed heated BLG in monomer, dimer, trimer and polymer form suggesting that the most of the covalent bonds were disulfide bridges. Glycated BLG showed almost the same electrophoretic pattern under both reducing and non-reducing conditions suggesting formation of only non-disulfide covalent bonds.

Figure S1. Protein profile of heated and glycosylated BLG on 12% SDS-PAGE gel under (A) non-reducing and (B) reducing conditions. Protein bands were stained with CBB.

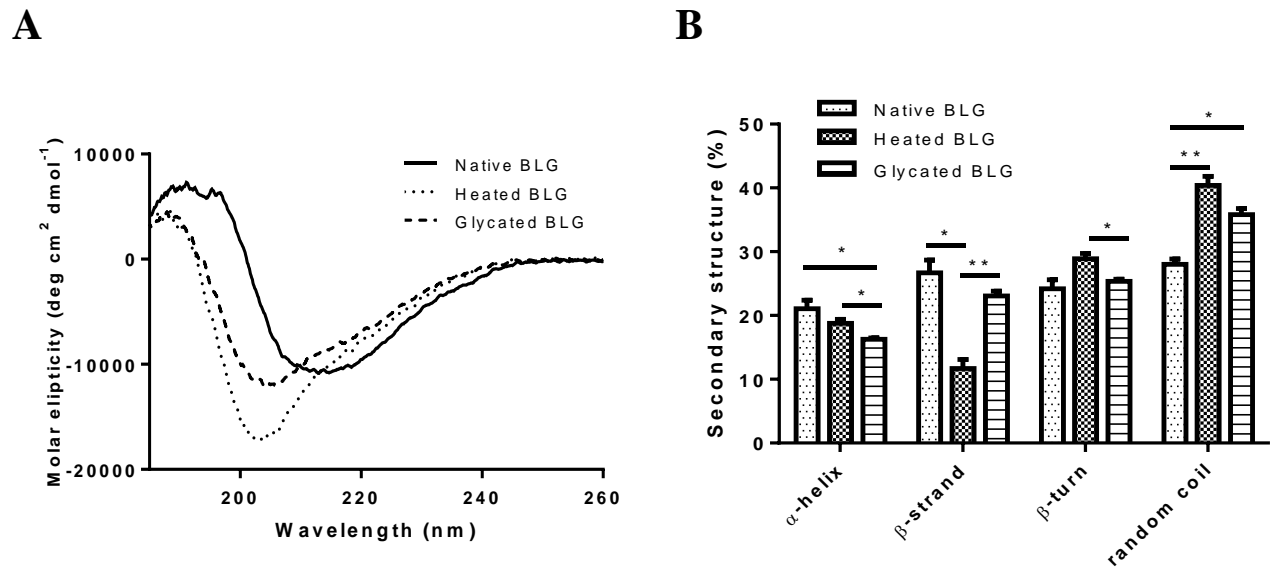

Figure S2. (A) CD spectra of native and glycosylated BLG in far-UV spectral range. (B) Percentages of the secondary structures were estimated by CONTIN algorithm available in CDPro package based on SP29 reference set. Secondary structure fractions were compared by Student's t-test. * and ** represent significance at $p < 0.05$ and 0.01 confidence level, respectively.

In addition, far-UV CD spectra showed significant difference in secondary structures between heated and glycated BLG (Fig. S2A). In comparison to native BLG, both heated and glycated BLG showed shift of peak minimum towards lower wavelengths, but peak of heated BLG was more profound indicating more significant loss of beta sheets. Indeed, estimation of secondary structure content using CONTIN algorithm showed significant difference between heated and glycated BLG in the content of α -helix, β -turn and β -strand (Fig. S2B). Glycated BLG was characterized with significantly ($P>0.01$) higher β -strand content, as well as lower α -helix and β -turn content ($P>0.05$), compared to heated BLG.

Taken together, the addition of sugar partially protects BLG from heat-induced denaturation, and structural changes induced by Maillard reaction are not the result of additive effect of thermal treatment and covalent binding of sugar. Maillard reaction is a complex process that results in unique protein modification rather than the simple sum of covalent attachment of sugar moieties and thermally induced structural changes. Therefore, it would have been very difficult to use heated BLG as a reference and interpret the results in comparison to the heated sample.
